

Primary beam splitter splits beams into two

Article Overview

A primary beam splitter divides an incident light beam into two separate beams, typically one transmitted and one reflected, according to a designed ratio.

Function and Principle

A beam splitter is an optical device that splits an incoming light beam into two paths: one that passes through the splitter (transmitted) and one that is reflected at an angle, often 90° to the incident beam. The splitting ratio, such as 50:50 or 70:30, is determined by the coating on the splitter's surface, which partially reflects and partially transmits light. Some beam splitters are designed to maintain polarization, while others are non-polarizing for general use.

Types of Beam Splitters

- **Cube Beam Splitters:** Constructed from two triangular prisms glued together, with a coated hypotenuse surface. Light entering the coated prism is split into transmitted and reflected beams, often at a 50/50 ratio.
- **Plate Beam Splitters:** Thin glass plates with a reflective coating on one surface, typically used at a 45° angle of incidence. They can split light according to a fixed ratio and often include anti-reflection coatings to reduce unwanted reflections.
- **Half-Silvered Mirrors:** Glass or plastic sheets with a thin metallic coating, reflecting part of the light and transmitting the rest, commonly used in photography and laser systems
